Abstract

Clotrimazole is an azole fungicide used as a human pharmaceutical that is known to inhibit cytochrome P450 (CYP) enzymatic activities, including several steroidogenic CYP. In a previous report, we showed that a 7 days exposure to clotrimazole induced the expression of genes related to steroidogenesis in the testes as a compensatory response, involving the activation of the Fsh/Fshr pathway. In this context, the aim of the present study was to assess the effect of an *in vivo* 21-d chronic exposure to clotrimazole (30 – 197 µg/L) on zebrafish testis function, i.e. spermatogenesis and androgen release. The experimental design combined (i) gene transcript levels measurements along the brain-pituitary-gonad axis (ii) 11-ketotestosterone quantification in blood and (iii) histology of the testes, including morphometric analysis. The chronic exposure led to an induction of steroidogenesis-related genes and *fshr* in the testes as well as *fshβ* in the pituitary. Moreover, increases of the gonado-somatic index and of the volume proportion of interstitial Leydig cells were observed in clotrimazole-exposed fish. In accordance with these histological observations, the circulating concentration of 11-KT had increased. Morphometric analysis of the testes did not show an effect of clotrimazole on meiotic (spermatocytes) or postmeiotic (spermatids and spermatozoa) stages, but we observed an increase in the number of type A spermatogonia, in agreement with an increase in mRNA levels of *piwill*, a specific molecular marker of type A spermatogonia. Our study demonstrated that clotrimazole is able to affect testicular physiology and raised further concern about the impact of clotrimazole on reproduction.

Keywords: clotrimazole, endocrine disruption, spermatogenesis, steroidogenesis, HPG axis, zebrafish

1. Introduction

Spermatogenesis is a cyclic and tightly regulated developmental process during which a small number of spermatogonial stem cells proliferate and differentiate to form a large number of spermatozoa (Nobrega et al. 2009; Schulz et al. 2010). Germ cells can only survive and develop in close and continuous relationship with Sertoli cells (Matta et al. 2002). Spermatogenesis is supported by testicular steroidogenesis, a multi-step process involving a cascade of enzymatic reactions and producing steroid hormones (Miller 1988; Parker and Schimmer 1995) that control various physiological functions (Miller 1988). Spermatogenesis and steroidogenesis are under control of the hypothalamus-pituitary-gonad (HPG) axis: hypothalamic gonadotropin-releasing hormone (GnRH) stimulates the release of pituitary gonadotropins, luteinizing hormone (Lh) and follicle-stimulating hormone (Fsh), that interact with their gonadal G protein-coupled receptors, Fsh receptor (Fshr) and Lh receptor (Lhcgr). Androgenic sex steroids synthesized in Leydig cells in response to gonadotropic stimulation interact with the androgen receptor (Ar) expressed by Sertoli or interstitial somatic cells in the testis (Burns and Matzuk 2002; Kumar 2005; Petersen and Soder 2006; Pierce and Parsons 1981). In fish, testicular expression sites of gonadotropin receptors overlap in Sertoli and Leydig cells (Garcia-Lopez et al. 2009; Ohta et al. 2007) and Fsh is a potent steroidogenic hormone (Kazeto et al. 2008; Planas et al. 1993). Follicle stimulating hormone activates the Fshr on Leydig and Sertoli cells to control steroidogenesis and spermatogenesis, respectively (Garcia-Lopez et al. 2009; Garcia-Lopez et al. 2010; Ohta et al. 2007; Schulz et al. 2010). In male fish, Leydig cells produce 11-oxygenated androgens, such as 11-ketotestosterone (11-KT), which stimulates spermatogenesis (Miura *et al.* 1991). Sertoli cells but not germ cells expressed functional receptors for both androgens and Fsh, so these cells act as regulatory interface between the endocrine system and the germ cells (Petersen and Soder 2006).

Azole fungicides inhibit cytochrome P450 (CYP) 51, 14 α -lanosterol demethylase, disrupting ergosterol synthesis and increasing cell permeability in fungi (Georgopapadakou 1998; Henry and Sisler 1984). Several azole fungicides such as ketoconazole or prochloraz also inhibit other CYP enzyme activities and have the capacity to alter gonadal steroidogenesis and reproductive function in fish (Ankley et al. 2007; Villeneuve et al. 2007a; Zhang et al. 2008a). For example, several azole compounds inhibit steroidogenic cytochrome P450 17 α -hydroxylase/17,20-lyase (Cyp17) and aromatase (Cyp19) in mammals and fish (Ayub and Levell 1987; Heneweer et al. 2004; Hinfrey et al. 2006b; Monod et al. 1993; Vinggaard et al. 2000). Data on the occurrence and fate of azole fungicides in the aquatic environment are scarce although the concentrations of several azoles such as clotrimazole, propiconazole, fluconazole and tebuconazole have been reported at concentrations ranging

from the low ng/L to the low µg/L range (Berenzen et al., 2005; Kahle et al., 2008; Kreuger, 1998; Peschka et al., 2007; Roberts and Thomas, 2006; Thomas and Hilton, 2004). Despite their occurrence in aquatic habitat, there exist very few studies on their *in vivo* endocrine-disrupting potencies in fish (Brown et al., 2011; Hinfrey et al., 2011).

In a previous short-term experiment of 7 days, we investigated the effect of clotrimazole on the pituitary-gonad axis at the molecular level in adult male zebrafish. Our data showed that clotrimazole induced a biological compensation as revealed by increased expression of steroidogenesis-related genes and protein *de novo* synthesis in Leydig cells while the 11-KT plasma concentration was not affected. Clotrimazole exposure also induced over-expression of pituitary *fshβ* and its testicular receptor *fshr*. These results suggested that Fsh/Fshr signalling is involved in the clotrimazole-induced steroidogenesis (Baudiffier et al. 2012; Hinfrey et al. 2011). Moreover, this raised the question if also spermatogenesis, a process regulated by androgens and Fsh (McLachlan et al. 2002; Plant and Marshall 2001; Schulz et al. 2010), would be affected by clotrimazole.

Therefore, the present study aimed at assessing the effect of a prolonged *in vivo* exposure of fish to clotrimazole on steroidogenesis and spermatogenesis, addressing the following questions: (i) Does biological compensation in response to inhibiting enzymatic activities still occur after a prolonged 21-d exposure of male fish to clotrimazole at similar concentrations as those previously used for the 7-d exposure experiment? (ii) Does a prolonged exposure have a significant effect on spermatogenesis?

2. Methods

The experimental design and most of the biological analyses have been described in a previous study (Baudiffier et al. 2012).

2.1. Animals and treatments

All experiments were approved by the ethical committee of the National Institute of Industrial Environment and Risks (INERIS). Wild type adult male zebrafish (*Danio rerio*, AB strain) were obtained from our breeding units (INERIS, Verneuil-en-Halatte, France). Fish were raised on a 14:10 light:dark cycle in a recirculated water system (Tecniplast, France) at 25.1 ± 1 °C. Clotrimazole (CLO, purity $\geq 98\%$) was purchased from Sigma-Aldrich (France) and all the stock solutions were prepared in dimethylsulfoxide (DMSO; Sigma-Aldrich).

Zebrafish were exposed to three concentrations of clotrimazole (30, 67 and 197 $\mu\text{g/L}$) or solvent alone (DMSO, 0.004 % v: v) for 21 days under semi-static conditions with a total renewal of the contaminated water every days (temperature: 25 ± 0.7 °C; pH: 8.01 ± 0.37 ; conductivity: 374.5 ± 27.6 $\mu\text{S/cm}$; dissolved oxygen: 5.8 ± 0.8 mg/L). Each condition contained 21 fish equally distributed in three replicates 4L-glass tanks. Water samples were collected from each condition at day 11 and day 18 at the time of water renewal ($t=0\text{h}$) and 24h later ($t=24\text{h}$).

2.2. Fish sampling

At the end of the exposure, fish were sacrificed in ice cold water and blood (2.5 or 5 μL) was collected. Liver, pituitary and brain were removed and preserved in RNA laterTM (Sigma-Aldrich, France) until quantification of gene expression. Testes were removed, weighted and preserved in RNA laterTM (Sigma-Aldrich, France) or fixed in Bouin's fluid for histological and immunohistochemistry experiments. Testis mass was determined to calculate the gonado somatic index (GSI, gonad wet mass/total body wet mass x 100).

2.3. Measurement of actual clotrimazole concentrations

The protocol was adapted from (Peschka et al. 2007) as described in (Baudiffier et al. 2012). Briefly, clotrimazole concentrations in control and exposure tanks were determined using solid phase extraction (SPE) followed by high-pressure liquid chromatography (HPLC) coupled to UV-Vis detection. An external calibration was used. The limit of detection (LOD) was 0.3 µg/L, the limit of quantification was 1.1 µg/L and the recovery of clotrimazole was higher than 90 % in all the experiments. The coefficient of variation, calculated from two replicates per condition, range from 0.4 to 18%.

2.4. Gene expression analysis

Transcript levels of genes along the brain-pituitary-gonad axis were measured, using a combination of genes involved in steroidogenesis and spermatogenesis (**table S1**). In testis tissue, expression of steroidogenic acute regulatory protein (*star*); hydroxyl- Δ -5-steroid dehydrogenase, 3 β - and steroid Δ -isomerase 1 (*hsd3b1*); cytochrome P450, family 17, subfamily A polypeptide 1 (*cyp17a1*); cytochrome P450, family 11, subfamily C, polypeptide 1 (*cyp11c1*; previously referred to as *cyp11b2*); hydroxysteroid (11- β) dehydrogenase 3a (*hsd11b3a*); cytochrome P450, family 19, subfamily A, polypeptide 1a (*cyp19a1a*); cytochrome P450, family 19, subfamily B, polypeptide 1a (*cyp19a1b*); luteinizing hormone / choriogonadotropin receptor (*lhcg*); follicle stimulating hormone receptor (*fshr*); were measured. The Sertoli cell markers insulin-like growth factor 3 (*igf3*), anti-müllerian hormone (*amh*) as well as the androgen receptor (*ar*) and the spermatogonial cell marker piwi-like 1 (*piwil1*) were also quantified. In pituitary tissue, expression of beta sub-unit of luteinizing hormone / choriogonadotropin (*lh β*) and follicle stimulating hormone (*fsh β*) were measured. In brain tissue, expression of gonadotropin-releasing hormones 3 (*gnrh3*) and steroidogenesis-related genes were also assessed. Indeed, in view of the impact of clotrimazole on testicular steroidogenesis, examination of brain steroidogenesis appears interesting to consider. In addition, the expression of drug metabolizing enzyme (DME) genes, such as phase I enzymes, i.e. cytochrome P450, family 1, subfamily A polypeptide 1 (*cyp1a1*), cytochrome P450, family 3, subfamily A polypeptide 65 (*cyp3a65*) or phase II conjugating enzymes, i.e. glutathione S-transferase, alpha-like (*gsta1*) and glutathione S-transferase *pi 1* (*gstp1*) was quantified in the liver (**table S1**). DMEs, known to be involved in xenobiotic and drug metabolism, are also key enzymes of catabolism for steroid hormones (Lee et al. 2003).

To measure genes expression levels, total RNA was extracted from testis, liver, brain or pituitary using Trizol Reagent (Life Technologies Inc., UK) following the manufacturer's instructions and complementary DNA for the real-time PCR reactions was generated using a Moloney Murine Leukemia Virus reverse transcriptase (M-

MLV RT, Promega, France). Gene expression was analyzed using an Eppendorf realplex 4 Master cycler ep gradient S (Eppendorf, France) as previously described by Baudiffier et al. (2012). Normalization to total RNA in association with calibration to a gene-specific mRNA standard curve was employed in organs. For RNA normalization, total RNA was previously adjusted at the same concentration using a Nanodrop ND-8000 spectrophotometer (Nanodrop Technologies, Wilmington, DE) for all samples before reverse transcription. Standard curves were generated for each gene, using specific primers and samples amplified by classic PCR. The concentration of these standards was measured using a Nanodrop ND-8000 spectrophotometer and adjusted to a concentration of 10^{-4} $\mu\text{g}/\mu\text{l}$ of cDNA and then serially diluted from 10^{-4} $\mu\text{g}/\mu\text{l}$ to 10^{-11} $\mu\text{g}/\mu\text{l}$. They were run in parallel to the samples to analyse in the rt-PCR to obtain the concentration in $\mu\text{g}/\mu\text{l}$ for each sample from the corresponding Cycle Treshold (Ct) value. This method, excluding housekeeping genes, was described in the literature. Then, a fold change in mRNA was obtained for each gene of clotrimazole-treated fish relatively to the mean value of the control group for the corresponding gene (Huggett et al. 2005; Villeneuve et al. 2007a).

2.5. Measurement of 11-KT concentrations

11-Ketotestosterone was quantified in blood samples by means of a competitive ELISA, following the manufacturer's instructions (11-KT EIA Kit, Cayman Chemical Company, U.S.A.). The mean $\text{EC}_{50} \pm$ standard deviation was 8.6 ± 0.7 pg/ml ($n = 6$ independent experiments). The calculated coefficient of variation between assays was 8 %, and the detection limit was $2.8 \text{ pg/ml} \pm 0.3 \text{ pg/ml}$.

2.6. Fluorescent immunohistochemistry and histology

After fixation in Bouin's fluid, testis were dehydrated in ethanol, cleared in toluene and embedded in paraffin, according to conventional procedures. Samples were sectioned at 5 μm (longitudinal sections). Sections were stained with Haematoxylin-Eosin for histology or mounted on gelatine-coated slides and processed for immunohistochemistry.

Fluorescent immunohistochemistry of Cyp17a1 and Cyp11c1 proteins in zebrafish testes has been performed as previously described (Baudiffier et al. 2012; Hinfrey et al. 2011). Briefly, sections were dewaxed and rehydrated, and antigens were unmasked. Tissue sections were then incubated for 1 h in a saturation PBS solution containing 0.2% Triton X-100 and 1% milk powder. Incubation with the primary antibody was performed overnight (1:300 with 0.5% milk powder in PBS) at room temperature. After rinsing, sections were

incubated for 1h30 with a goat anti-rabbit antibody coupled to Alexa fluor 594 (1:200 with 0.5% milk powder in PBS).

For morphometric analysis, the protocol was adapted from (Feitsma et al. 2007). The mass of germ cells and other components (i.e. , somatic cells including Leydig cells, blood and lymphatic vessels, connective tissue and empty spaces) were determined by light microscopy using a 352-intersection grid. Eight fields chosen randomly (3016 points or 8 fields of 352-intersection grid) were scored for each animal. Intersection points over tissue components were classified as being over one of the following cell types: type A spermatogonia, type B spermatogonia, spermatocytes, spermatids, spermatozoa or 'others', as defined above (i.e. Leydig cells, blood vessels etc.). A detailed morphological description allowing the identification of the different germ cell types in zebrafish has been given previously (Leal et al., 2009); cell type identification is mainly based on the changes in the size of the nuclei, the amount of heterochromatin, visibility of nucleoli, and number of cells within a spermatogenic cyst. The scores were first expressed as the volume fraction per testis tissue component. The mass (mg) of each testis component was then determined as the product of the testis mass (mg) x volume fraction of spermatogenic parenchyma (~0.8) x volume fraction of specific tissue component. The volume fraction of spermatogenic parenchyma was used as a correction factor in order to exclude the mass of the testes capsule, the efferent ducts, and connective tissue associated with testes.

The Leydig cell volume fraction was determined by light microscopy using a 713-intersection grid. Eight fields chosen randomly (5704 points or 8 fields of 713-intersection grid) were scored for each animal. Analysis was performed for 5 fish of each condition. Intersection points were classified as being over Leydig cells or not. Results were expressed in percentage of Leydig cells compared to the total number of cells. The mass (mg) of Leydig cells was then determined as the product of the testis mass (mg) x volume fraction of spermatogenic parenchyma (~0.8) x volume fraction of Leydig cells component. The volume fraction of spermatogenic parenchyma was used as a correction factor in order to exclude the mass of the testes capsule, the efferent ducts, and connective tissue associated with testes.

2.7. Data analysis

One way analysis of variance (ANOVA) was performed to test for differences between treatments. Then, differences among treatments were determined using a post hoc test (Tukey Honestly Significant Difference). Normality of the data was previously assessed using a Shapiro test and homogeneity of variance was also verified using the Bartlett test. Non-normally distributed data were log-transformed prior to analysis and a nonparametric Kruskal Wallis test, followed by a Multiple Comparison test, was used when data did not meet parametric assumptions. For gene expression analysis in the pituitary, a Mann and Whitney U-test was employed to compare gene expression levels between the highest clotrimazole-exposed fish and the control fish only.

Levels of gene expressions were expressed as fold changes relative to the average value of the control. Statistical analyses, including principal component analysis (PCA), were conducted using RTM (R 2.13.1, software, R development Core Team). All data are presented as mean $\pm$ SEM. Significance level (p) was fixed at 0.05 (p<0.05 *; p<0.01 **; p<0.001 ***).

3. Results

3.1. Water chemistry

Concentrations of clotrimazole measured in water just after adding clotrimazole ($t=0$ h) were 30, 67 and 197 $\mu\text{g/L}$ for the low, medium, and high contaminations, respectively (**table 1**). Concentrations declined by 32, 17 and 22%, respectively, after 24 h ($t=24$ h). For each condition, two measurements were performed (at day 11 and day 18). The results showed that the concentrations were stable over time and concentrations of exposure. Control water samples were all below the limit of detection, i.e. 0.3 $\mu\text{g/L}$.

3.2. Biometric parameters

No mortality or any abnormal behavior was recorded in control and clotrimazole-exposed groups during the study. Furthermore, no significant differences were measured among groups for body mass or length (**table 2**). In fish exposed to the highest concentration of clotrimazole, a strong (30%) and significant increase of the GSI was measured as compared to control fish (**table 2**).

3.3. Expression of genes involved in testicular steroidogenesis

The mRNA levels of steroidogenesis-related genes in testes, i.s. gonadotropin receptors, *star* and several genes coding for steroidogenic enzymes were analysed in control and clotrimazole-exposed fish (**Fig.1**). Among nine genes assayed by Q-PCR, an increase in transcript levels was observed for five genes after 21 days of exposure to the highest concentration of clotrimazole.

The expression of *fshr* but not of *lhcr* was significantly 1.69-fold up regulated at the highest concentration of clotrimazole ($p = 0.0013$). The levels of *star* mRNA increased 1.77-fold relative to the controls ($p = 0.0094$). Still at the highest concentration, the transcript levels of *cyp17a1*, *cyp11c1* and *hsd11b3a* were up-regulated 2.18-, 2.13- and 1.41 fold, respectively ($p = 0.00001$, $p = 0.0015$, $p = 0.0013$). The expression of *fshr* was significantly correlated with these steroidogenic-related genes: *star* (Spearman 's rank correlation coefficient $r = 0.59$; $p < 0.001$), *cyp17a1* ($r = 0.43$; $p < 0.001$), *cyp11c1* ($r = 0.53$; $p < 0.01$) and *hsd11b3a* ($r=0.63$, $p<0.001$). Besides, these steroidogenic-related genes were significantly correlated with each other (data not shown)

suggesting that Fsh coordinates the stimulatory effects of these genes. Interestingly, *cyp19a1a* gene expression was down-regulated at 30 and 67 µg/L, and statistical significance was reached in the 67 µg/L clotrimazole-exposed group. However, no effect was observed at the highest concentration.

3.4. Gene expression in brain and pituitary

In brain tissue, transcript levels of genes encoding brain steroidogenic enzymes, oestrogen and androgen receptors as well as *gnrh3* were compared between control and clotrimazole-exposed groups (**table 3**). Clear and statistically significant changes in transcript levels were not found for any of the genes at all concentrations of clotrimazole. While a two-fold induction of *cyp19a1a* expression was measured in fish exposed to 30 and 197 µg/L of clotrimazole, the high variability observed between individuals, may contribute to the lack of statistical significance.

In the pituitary, transcript levels of *fshβ* and *lhβ* were assessed for the 197 µg/L clotrimazole-exposed group and compared to untreated fish. We only assessed gonadotropin gene expression at the highest concentration because we observed a strong and significant induction of the GSI, of several steroidogenesis-related genes, and of *fshr* transcript levels in this group. The results showed that *fshβ* was increased by 3.6-fold, but expression of *lhβ* was unchanged (**Fig.2**).

3.5. Cyp17a1 and Cyp11c1 immunostaining in the testes

Using specific polyclonal antibodies, fluorescent immunohistochemistry was performed in testis sections after 21 days of exposure to assess the effect of clotrimazole on Cyp17a1 and Cyp11c1 protein occurrence (**Fig.3**). The two proteins were localized in interstitial Leydig cells and increased immunostaining was observed for both proteins from 67 µg/L of clotrimazole. This increase became very marked at the highest level of clotrimazole treatment (197 µg/L) especially for the Cyp11c1 protein (**Fig.3A and .3B**). These results are in accordance with the data on *cyp17a1* and *cyp11c1* genes expression.

3.6. 11-ketotestosterone concentrations in blood

Clotrimazole significantly affected blood 11-KT concentrations as compared to the control group (**Fig.4**). A concentration-dependent increase was measured with a significant effect at the highest concentration of clotrimazole. Moreover, we noticed a higher inter-individual variation in clotrimazole-exposed groups compared to the solvent control group.

3.7. Expression of spermatogenesis-related genes

Transcription of genes involved in spermatogenesis was assessed in testes of control and clotrimazole-exposed fish after 21 days of exposure (**Fig.5**).

The androgen receptor *ar* that is expressed in Sertoli and interstitial cells but not in germ cells was significantly up-regulated for all clotrimazole treatments with a similar fold induction whatever the exposure concentration. Transcriptional levels of the two Sertoli cells markers *amh* and *igf3* were also examined. Anti-müllerian hormone *amh* expression was unchanged whereas *igf3* expression was induced in the 67 µg/L clotrimazole-exposed group ($p= 0.02$) but not at the highest clotrimazole concentration. Finally, transcript level of the spermatogonial marker *piwill* was significantly up-regulated at the highest clotrimazole concentration (1.38-fold for 197 µg/L).

3.8. Expression of genes involved in the catabolism of steroid hormones

Transcript levels of different genes encoding for drug metabolizing enzymes (DMEs) were assessed after 21 days of exposure in testis and in liver (**Fig.S1, Fig.S2**). In the liver, transcriptional levels of phase I DMEs, i.e. *cyp1a* and *cyp3a65*, and of phase II conjugating enzymes, i.e. *gstal* and *gstp1*, remained unchanged in clotrimazole-exposed groups compared to the control group (**Fig.S1**). However, in testis, *cyp3a65* expression was significantly up-regulated (**Fig.S2**).

3.9. Principal Component analysis (PCA)

A PCA was performed in order to have an overview of correlations between the different endpoints measured in the testis and in the blood (**Fig.6**). The factor 1 explained 34.02% of the data variability whereas the factor 2

explained 16 % of the data variability. A plot with respect to this two principal components revealed that expression of all endpoints influenced variation in the negative direction along factor 1. Along factor 2, a strong association between several steroidogenesis-related genes involved in androgen synthesis (*star*, *cyp17a1* and *cyp11c1*) was observed. This group of genes was closely associated with *igf3*, a Sertoli cell marker and *piwill*, a spermatogonia type A marker (**Fig.6A**). A close association between 11-KT and GSI was also found. These two parameters were significantly affected in the highest clotrimazole-exposed group and increase GSI might be a consequence of elevated 11-KT production. Interestingly, genes related to estrogens biosynthesis (i.e., *cyp19a1a* and *cyp19a1b*) and ER-signalling pathway (i.e., *esr1*, *esr2a*, *esr 2a*) were closely associated and located at the opposite side of those related to androgen biosynthesis. The genes involved in the metabolism of xenobiotic and endogenous hormones (*cyp1a* and *cyp3a65*) were closely associated and localized at the opposite from the biological parameters related to androgen synthesis. Although clotrimazole differently affected the expression of genes encoding for gonadotropin receptors, they were closely associated together with androgen receptor and *amh*, another Sertoli cell marker. A second plot, representing condition of exposures, showed a strong difference between the 197 µg/L clotrimazole-exposed group that influenced variation along factor 1 compared to the other groups including control and the two other clotrimazole-exposed groups (**Fig.6B**) showing that all the selected genes allowed to discriminate the different treatments to clotrimazole.

3.10. Histology and morphometric analysis of the testes

Histological analysis showed an enlargement of the interstitial space in fish exposed to clotrimazole, as indicated by white arrows (**Fig.7A**, control; **Fig.7B**, 197 µg/L clotrimazole). Interestingly, morphometric analysis revealed a significant 2-fold increase of Leydig cell mass (**Fig.7C**). Finally, quantitative morphometric analysis of testis tissue components was realized in the group exposed to 197 µg/L clotrimazole and the control group (seven males for each group). We focused on the highest clotrimazole concentration since it evoked the most clear effects regarding Leydig cells, target gene expression and GSI. In control individuals, the mass of germ cells, i.e. spermatogonia, spermatocytes, spermatids and spermatozoa, agrees with previously reported data in adult male zebrafish (de Waal et al. 2009). In exposed-fish, a significant 2-fold increase of type A spermatogonia (but not type B) was quantified (**Fig.7D**).

4. Discussion

The present work investigated the chronic effects of clotrimazole on two related processes, testicular steroidogenesis and spermatogenesis, after 21 days of exposure of zebrafish. A biological compensation of the steroidogenic enzymes inhibition by clotrimazole was revealed, with an up-regulation of genes coding for steroidogenic enzymes, pituitary *fsh β* , and its testicular receptor *fshr*. This underlines the critical role of the Fsh/Fshr signalling pathway in mediating the effects of clotrimazole on testicular steroidogenesis. In accordance with inducing Leydig cell steroidogenesis and stimulating the Fsh/Fshr pathway, transcript levels of the Sertoli cell genes *igf3* and *ar* were increased, as well as the 11-KT circulating levels. Furthermore, morphometric analysis of the testes demonstrates that spermatogenesis was impacted by clotrimazole as shown by the increase of the mass of type A spermatogonia in clotrimazole-exposed fish, in accordance with the up-regulation of a marker gene for this germ cell type, *piwill*.

4.1. Chronic exposure to clotrimazole led to activation of Fsh/Fshr signalling and over-compensation of the steroidogenic parameters

In the present study, we investigated the effects of clotrimazole on the brain-pituitary-gonadal axis, in particular the impact on testicular steroidogenesis after 21 days of exposure. We showed that clotrimazole up-regulated the expression of steroidogenesis-related genes (*star*, *cyp17a1*, *cyp11c1*). Principal Component Analysis (PCA) revealed that these endpoints were correlated. Cyp17a1 and Cyp11c1 protein expression was also increased in Leydig cells and 11-KT blood levels were elevated. Induction of steroidogenesis-related genes agrees with recent work on adult male fathead minnow or medaka exposed 21 days to azoles, i.e. ketoconazole or prochloraz (Ankley et al. 2007; Villeneuve et al. 2007a). Clotrimazole is known to inhibit several CYP enzyme activities in fish and mammals; including Cyp19 and Cyp17 (Ayub and Levell 1987; Hinfray et al. 2006b; Monod et al. 1993; Schuster 1985). This inhibition of enzymatic activities in testis tissue can lead to reduced 11-KT release, as noticed in an *in vitro* zebrafish testicular explant culture system (Hinfray et al. 2011). For that reason, stimulation of the steroidogenic system *in vivo* was interpreted as a biological compensation in response to enzyme inhibition (Ankley et al. 2007; Baudiffier et al. 2012; Hinfray et al. 2006b; Villeneuve et al. 2007b; Zhang et al. 2008a). However, in the present study, we observed an increase of circulating 11-KT concentrations surmounting control levels, suggesting that an exposure to clotrimazole for 21 days led to an over-compensation.

We postulate that clotrimazole initially depressed plasma androgen levels, provoking a compensatory response via Fsh, including an increased *de novo* synthesis of steroidogenic enzymes, such that 11-KT blood levels were normal after 7 days of exposure (Baudiffier et al. 2012), but exceeded normal levels after 21 days of exposure (present study). In recent works on adult male fathead minnows exposed for 21 days to ketoconazole or fadrozole, plasma concentration of 11-KT was not affected (Ankley et al. 2007) or induced (Ankley et al. 2002), respectively. In mammals, plasma and intra-testicular concentrations of testosterone were increased following long-term exposure to azoles (**table 4**). Taken together, these studies and our study suggest that the relationship between azole exposures and final androgen plasma concentrations cannot be predicted easily. This is probably due to the balance between a direct inhibition of enzyme activities and a compensatory response that stimulates testicular steroidogenic gene expression by gonadotropin. The impact of azole on plasma 11-KT may also depend on the biological model, the tested azole, or the exposure conditions (concentration and duration). Furthermore, the 11-KT concentration is a result of its production, degradation, and excretion. So, an important point to consider is steroid hormone degradation (Lou et al. 2004) by DME, expressed in the liver but also in the gonads. For example, in the present study, we observed an induction of *cyp3a65* mRNA transcript level in testes of the group exposed to the highest clotrimazole concentration. This increased gene expression could lead to Cyp3a65 enzyme production and influence circulating 11-KT concentrations. In addition, we noticed an inhibition of *cyp19a1* aromatase in the testes following clotrimazole contamination whereas expression of other enzymes involved in androgen production was induced, such as *cyp17a1* and *cyp11c1*. Reduced aromatisation of androgens could contribute to increasing substrate availability for 11-KT synthesis.

The increase in testicular *fshr* and pituitary *fsh β* expression is consistent with a compensatory response supporting the role of Fsh/Fshr-signalling in the clotrimazole-induced steroidogenesis, as demonstrated in our previous 7-days experiment (Baudiffier et al. 2012), if the assumed initial decrease of plasma 11-KT concentration would stimulate pituitary Fsh synthesis and release. However, a change in *gnrh3* expression, an important regulator of gonadotropin release in teleost species possessing two GnRH variants (Kobayashi et al. 1997; Steven et al. 2003), was not demonstrated in our study.

As clotrimazole can directly inhibit CYP activities in testes (Ayub and Levell 1987; Hinfray et al. 2006a; Monod et al. 1993), it was also interesting to investigate the effects of clotrimazole on brain steroidogenesis. Indeed, in teleost fish, the brain possesses high aromatase activity (Pasmanik and Callard 1985) due to the strong expression of the *cyp19a1b* gene coding for aromatase B protein in radial glial cells (Forlano et al. 2001; Menuet et al. 2005). Furthermore, a recent study suggested that radial glial cells express the whole set of key

steroidogenic enzymes necessary to produce active steroids from cholesterol (Diotel et al. 2011). Our data showed that clotrimazole had no effect on expression of steroidogenesis-related genes in brain tissue. However, considering that these genes are expressed in specific area of the brain, we cannot exclude a dilution effect has masked possible, more subtle changes, since mRNA levels were measured in the whole brain. This reasoning also applies to GnRH-producing neurones, so that mRNA quantification in specific areas of the brain may provide more relevant data in future experiments.

4.2. Biological relevance of Fsh-driven clotrimazole-disrupted steroidogenesis on spermatogenesis

In the present study, we assessed the effect of clotrimazole on testicular physiology, i.e. steroidogenesis and spermatogenic function at the histological and molecular level. Morphometric analysis of germ cells showed a significant effect in the number of type A spermatogonia in the 197 µg/L clotrimazole-treated fish compared to control fish. This result is in agreement with the induction of the germ cell marker *piwill* expression (formerly known as *ziwi*), which is a component of a germline-specifying structure called nuage and expressed strongly and exclusively in type A spermatogonia of zebrafish (Chen SX et al. *in revision*). This increase of type A spermatogonia could be related to molecular changes in Sertoli cells, which are in close contact with germ cells and provide physical, nutritional and regulatory support to the developing germ cells (Griswold 1995; Petersen and Soder 2006). It is also of interest to notice that Sertoli cells that express the highest level of *ar* mRNA, are in contact with early spermatogonia (de Waal et al. 2008). This is consistent with the notion that these Sertoli cells respond to 11-KT, resulting in a stimulation of spermatogonial proliferation and differentiation (de Waal et al. 2008; Miura et al. 2001a; Miura et al. 1991). Furthermore, it has been demonstrated in eel testes that *fshr* is expressed in Leydig cells and high Fshr immunoreactivity was found in Sertoli cells surrounding type A and B spermatogonia (Ohta et al. 2007). In the present study, the observed increase in the mass of type A spermatogonia in adult male zebrafish is in agreement with an induction of the *ar* and *fshr* mRNA.

In accordance with an Fsh/Fshr signalling activation, we also observed an induction of *igf3*, which is under the control of Fsh and androgens in Sertoli cells. *Igf3* has been recently discovered in zebrafish, medaka and Nile tilapia and is specifically expressed in gonadal tissue (Wang et al. 2008). Igf3 belongs to insulin growth factor (IGF) family, which is known to stimulate spermatogenesis in vertebrates (Le Roy et al. 1999), including fish (Laird 1999).

An important result of our study was that morphometric analysis clearly demonstrated an increase in the mass of Leydig cells in clotrimazole-exposed fish. This is in accordance with an increase in circulating 11-KT concentrations and illustrates the stimulation of the steroidogenic system triggered by the Fsh/Fshr pathway. At present, it is not known why elevated Fsh-signalling and androgen levels did not result in an increase in the mass of spermatogonia B, spermatids and spermatozooids. As shown in **table 4**, an increased mass of interstitial Leydig cell has also been observed in fish exposed to clotrimazole and ketoconazole (Ankley et al. 2007; Brown et al. 2011), but the precise mechanism of action has not been described. It seems reasonable to assume that an increase in Leydig cell volume can partially explain the elevation of circulating 11-KT concentrations, as these cells are responsible for androgen production.

In conclusion, this study showed that expression of steroidogenesis-related genes in testicular tissue remained induced after 21 days of exposure. Induction of *fsh β* , *fshr* and *igf3* is consistent with and activation of Fsh/Fshr signalling in stimulating Leydig cells steroidogenesis. In comparison with 7 days-exposure period to clotrimazole, we observed in the present study an induction of blood 11-KT concentrations after 21 days of exposure. In parallel, an increase of GSI and a duplication of the mass of Leydig cells were observed. This over-compensation was not followed by a drastic adjustment of spermatogenesis as the proportion of most germ cells remained largely unchanged, except for an increase in the early spermatogonial generations. This study highlights the relevance of studying a network of functional genes along the brain-gonad axis in parallel with histological analysis at the testicular level to study the effect of clotrimazole as an endocrine disruptor. The present study contributes to progress in our understanding of the molecular mechanisms of clotrimazole and its impact on testis physiology.

Acknowledgments

This work was funded by a grant of the French ministry of Ecology P189-NEMO to FB, and by the European Union LIFECYCLE projects no FP7-222719 to RWS. DB was supported by a doctoral fellowship from ANRT and INERIS. We thank Dr. Alexis Fostier (INRA, Rennes, France) for comments on the manuscript. We thank Benjamin Piccini for his technical assistance.

Figure caption

Fig.1: Expression of gonadotropin receptors and of genes involved in testis steroidogenesis of adult male zebrafish following a 21 days exposure to clotrimazole. Data are presented as the fold change in gene expression relative to the control (mean $\pm$ SEM; n = 9 - 15 fish for each condition). An asterisk indicates a significant difference compared to control group (* $p \leq 0.05$, ** $p \leq 0.01$, *** $p \leq 0.001$).

Fig.2: Expression of gonadotropins beta sub-unit genes (*fsh β* and *lh β*) in pituitary of adult male zebrafish following a 21 days exposure to clotrimazole (197 μ g/L). Data are presented as the fold change in gene expression relative to the control (mean $\pm$ SEM; n = 14 - 18 fish for each condition). An asterisk indicates a significant difference compared to control group (* $p \leq 0.05$, ** $p \leq 0.01$).

Fig.3: Change in (A) Cyp17a1 and (B) Cyp11c1 protein labelling in zebrafish testes by fluorescent immunohistochemistry after a 21 days exposure to clotrimazole. Immunoreactivity was localized in Leydig cells and observed in all groups. Red: Cyp17a1 or Cyp11c1 immunostaining, blue: Hoechst staining. N = 6 fish /condition. Pictures are representatives of the 6 individuals analyzed as regards the staining patterns. Scale Bars = 50 μ m (white).

Fig.4: Plasma concentrations of 11-KT in adult male zebrafish following a 21 days exposure to clotrimazole. Data are expressed in pg/ml (mean $\pm$ SEM; N = 15 - 21 fish /condition). 11-KT= 11 ketotestosterone (* $p \leq 0.05$).

Fig. 5: Expression of Sertoli and germ cells localized-genes in testes of adult male zebrafish following a 21 days exposure to clotrimazole. Data are presented as the fold change in gene expression relative to the control (mean $\pm$ SEM, n = 11 - 15 fish for each condition). An asterisk indicates a significant difference compared to control group (* $p \leq 0.05$, ** $p \leq 0.01$).

Fig.6: Principal Component Analysis (PCA) of testicular gene expressions data as well as GSI and plasma concentration of 11-KT in adult male zebrafish for control fish and clotrimazole-exposed fish: figure 6A is a plot of the two dimensional PCA and figure 6B is a trajectory plot representing each treatment groups. The 95% confidence ellipses were drawn around each group (green: solvent control, yellow: clotrimazole 28 $\mu\text{g/L}$, brown: clotrimazole 67 $\mu\text{g/L}$, red: clotrimazole 197 $\mu\text{g/L}$).

Fig.7: Zebrafish testicular structure following a 21 days exposure to 197 $\mu\text{g/L}$ clotrimazole: zebrafish testis sections from control fish (A), or from clotrimazole-exposed fish (B). % of Leydig cells in testicular tissue from control fish or clotrimazole-exposed fish ($n=3-5$) (C). Morphometric analysis (D) of zebrafish testis sections from control group (empty white circle, $n = 5$) or from the 197 $\mu\text{g/L}$ clotrimazole-exposed group (full dark circle, $n = 6$) following a 21 days exposure. Data are represented as mass (mg) of testicular cell types: SPGA: spermatogonia A, SPGB: spermatogonia B, SPC: spermatocytes, SPT: spermatids, SPZ: spermatozoa and others.

Fig.S1: Expression of phase I drug metabolizing enzymes (DMEs) and phase II conjugating enzymes genes as well as steroid receptors in the liver of adult male zebrafish following a 21 days exposure to clotrimazole. Data are presented as the fold change in gene expression relative to the control (mean $\pm$ SEM; n = 3 - 9 fish for each condition). An asterisk indicates a significant difference compared to control group.

Fig.S2: Expression of drug metabolizing enzymes (DMEs) genes in testes of adult male zebrafish following a 21 days exposure to clotrimazole. Data are represented as the fold change in gene expression relative to the control (mean $\pm$ SEM; n = 9 - 10 fish for each condition). An asterisk indicates a significant difference compared to control group (* $p \leq 0.05$).

Table 1: Clotrimazole concentrations ($\mu\text{g/L}$) measured in water just after contamination ($t=0\text{h}$) and 24h later ($t=24\text{h}$)

	Solvent control	contamination		
		low	medium	high
t0h	< LOD	30.2 ± 1.6	66.8 ± 0.3	197.3 ± 6.4
t24h	< LOD	20.5 ± 0.8	55.5 ± 7.1	153.6 ± 3.0

LOD = Limit of detection

Table 2: Biometric parameters of fish after 21 days of chronic treatment with various concentrations of clotrimazole

Group		N	body weight (mg)	gonad weight (mg)	body lenght (cm)	GSI (%)
control	solvent	21	486 ± 103	8.3 ± 4.1	3.70 ± 0.27	1.6 ± 0.5
clotrimazole	low (29 µg/L) ¹	20	513 ± 133	8.9 ± 4.0	3.82 ± 0.27	1.7 ± 0.6
	medium (67 µg/L) ¹	21	454 ± 133	8.0 ± 4.7	3.71 ± 0.27	1.6 ± 0.8
	high (197 µg/L) ¹	21	523 ± 119	10.3 ± 3.9	3.83 ± 0.24	2.0 ± 0.9*

¹ Measured concentrations just after adding clotrimazole in water

* significant difference compared to control group (ANOVA paramétrique p ≤ 0.05)

GSI = Gonado somatic index; N = number of fish

Table 3: Effect of a 21 days exposure to clotrimazole on brain gene expression. Results are presented as ratio of clotrimazole-treated to control fish

Experimental groups	<i>genes</i>											
	<i>star</i>	<i>hsd3b1</i>	<i>cyp17a1</i>	<i>cyp11c1</i>	<i>hsd11b3a</i>	<i>cyp19a1a</i>	<i>cyp19a1b</i>	<i>gnrh3</i>	<i>ar</i>	<i>esr1</i>	<i>esr2b</i>	<i>esr2a</i>

Clotrimazole 197 µg/L	1.28 ± 0.06	1.20 ± 0.27	1.05 ± 0.08	0.84 ± 0.06	1.07 ± 0.17	1.97 ± 0.47	0.73 ± 0.21	0.58 ± 0.13	0.99 ± 0.06	1.18 ± 0.21	1.02 ± 0.14	1.17 ± 0.15

Table 4 : Morphometric analysis of the testes following several azole or triazole exposures and impact on GSI

reference	species	azole	time of exposure	concentration / duration	steroidogenesis	T /11-KT	GSI and morphometric analysis of the gonads
Brown - 2011	zebrafish (<i>Danio rerio</i>)	clotrimazole (CYPs inhibitor)	juvenile to adult (37 - 133 dph)	2.9 and 43.7 µg/L (96 days)	<i>hsd17b3, cyp19a1a</i> (-)	11-KT reduced	- increase in the GSI - increase in the proliferation of Leydig cells - germ cell development was significantly more advanced based on the proportions of spermatids and spermatozoa compared with spermatocytes and spermatogonia
Hinfray - 2011	zebrafish (<i>Danio rerio</i>)	clotrimazole (CYPs inhibitor)	adult	50 - 500 µg/L (7 days)	<i>cyp17a1</i> (++)	11-KT unchanged	- spermatogonia type A were observed more frequently
Baudiffier - 2012	zebrafish (<i>Danio rerio</i>)	clotrimazole (CYPs inhibitor)	adult	71 - 258 µg/L (7 days)	<i>star, cyp17a1, cyp11c1</i> (++)	11-KT unchanged	
Ankley - 2007	fathead minnow (<i>Pimephales promelas</i>)	ketoconazole (CYPs inhibitor)	adult	6 - 400 µg/L (21 days)	<i>cyp11a</i> and <i>cyp17a1</i> (++)	T unchanged	- increase in the GSI - marked proliferation of interstitial (Leydig) cells - interstitial cells have more rounded nuclei and more cytoplasm
Ankley - 2002	fathead minnow (<i>Pimephales promelas</i>)	fadrozole (aromatase inhibitor)	adult	2 - 50 µg/L (21 days)	not measured	T / 11-KT induced	- increase in the GSI - enlarged seminiferous tubule, accumulation of sperm in the testes - lack of germinal epithelium
Panter - 2004	fathead minnow (<i>Pimephales promelas</i>)	fadrozole (aromatase inhibitor)	adult	51.7 - 95.5 µg/L (21 days)	not measured	not measured	- increase in the GSI
Navarro-Martin - 2009	sea bass (<i>Dicentrarchus labrax</i>)	fadrozole (aromatase inhibitor)	sexually undifferentiated (90–150 dph)	100 mg.kg ⁻¹ food twice a day (60 days)	not measured	not measured	- increase in the GSI
Goetz - 2009	rat	triadimefon (CYPs inhibitor)	adult	126 mg/kg body weight/day (30 days)	not measured	T induced (plasma and intra-testicular)	- no change in the gonad weight
Turner - 2000	rat	anastrozole	adult	200 mg/L	not measured	T induced	- increase in the GSI

(aromatase
inhibitor)

(63 days)

(plasma and intra-
testicular)

- spermatogenesis was grossly normal
- 10% of rats had testes that appeared to contain only Sertoli cells

GSI: Gonado Somatic Index; *dph*: days post hatch
